

A brief introduction to quantum error correction

Andrew S. Darmawan

Yukawa Institute for theoretical physics

July 2, 2020

The big obstacle to building real-world quantum information technology is **noise**.

Quantum error correction is a proposed method to actively protect quantum information against noise.

Classical computers

- ▶ **Classical computers:** Basic unit of information is a bit $\{0, 1\}$. Errors on bits due to physical noise during computation are extremely rare.

Quantum computers

- ▶ **Quantum computers:** The basic unit of information is the qubit:

$$\alpha|0\rangle + \beta|1\rangle \quad (1)$$

In current architectures, the probability of error per gate is at best $\sim 10^{-2} - 10^{-3}$. Errors will affect output.

- ▶ Merely *storing* quantum information is difficult.

Quantum error correction

- ▶ **Threshold theorem:** Arbitrary long quantum computations can be efficiently performed with arbitrarily high accuracy provided the error rate is below some threshold value.
- ▶ This is possible due to **Quantum error correcting codes**, where a single logical qubit is encoded into the collective state of many quantum particles.

Quantum error correction: challenges

- ▶ It is not possible to copy arbitrary quantum states (no cloning theorem).
- ▶ Superpositions must be preserved (measurements can't collapse wavefunction)
- ▶ Many types of error must be corrected.

Pauli operators

- ▶ Single qubit Pauli operators:

$$X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, Y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

$$XZ = -ZX, \quad X^2 = Y^2 = Z^2 = I, \quad XZ = iY$$

- ▶ Single qubit Pauli operators with the identity form a basis for 2×2 matrices.

Pauli operators

- ▶ (n -qubit) Pauli operators are formed by tensor products $\otimes_{i=1}^n P_i$ where P_i are single qubit Pauli operators and the identity matrix E.g.

$$X_1 Y_3 Z_4 := X \otimes I \otimes Y \otimes Z \quad (2)$$

- ▶ Eigenvalues of Pauli operators are ± 1 .
- ▶ Any two n -qubit Pauli operators either commute or anti-commute. E.g.

$$\begin{aligned}(X \otimes I)(Z \otimes Z) &= XZ \otimes Z \\ &= -ZX \otimes Z = -(Z \otimes Z)(X \otimes I)\end{aligned}$$

$$\begin{aligned}(X \otimes X)(Z \otimes Z) &= XZ \otimes XZ \\ &= (-ZX) \otimes (-ZX) = (Z \otimes Z)(X \otimes I)\end{aligned}$$

Types of noise in quantum computers

- ▶ Noise of a single qubit interacting with an environment

$$\rho \mapsto \sum_k E_k \rho E_k^\dagger \quad (3)$$

- ▶ Common types of noise

- ▶ Bitflip: $(1 - p)\rho + pX\rho X$

$$\alpha|0\rangle + \beta|1\rangle \rightarrow \alpha|1\rangle + \beta|0\rangle \quad (4)$$

Types of noise in quantum computers

- ▶ Noise of a single qubit interacting with an environment

$$\rho \mapsto \sum_k E_k \rho E_k^\dagger \quad (3)$$

- ▶ Common types of noise

- ▶ Bitflip: $(1 - p)\rho + pX\rho X$

$$\alpha|0\rangle + \beta|1\rangle \rightarrow \alpha|1\rangle + \beta|0\rangle \quad (4)$$

- ▶ Phase flip: $(1 - p)\rho + pZ\rho Z$

$$\alpha|0\rangle + \beta|1\rangle \rightarrow \alpha|0\rangle - \beta|1\rangle \quad (5)$$

Types of noise in quantum computers

- ▶ Noise of a single qubit interacting with an environment

$$\rho \mapsto \sum_k E_k \rho E_k^\dagger \quad (3)$$

- ▶ Common types of noise

- ▶ Bitflip: $(1 - p)\rho + pX\rho X$

$$\alpha|0\rangle + \beta|1\rangle \rightarrow \alpha|1\rangle + \beta|0\rangle \quad (4)$$

- ▶ Phase flip: $(1 - p)\rho + pZ\rho Z$

$$\alpha|0\rangle + \beta|1\rangle \rightarrow \alpha|0\rangle - \beta|1\rangle \quad (5)$$

- ▶ Depolarising: $(1 - p)\rho + p/3(X\rho X + Y\rho Y + Z\rho Z)$

Simple example: Repetition code

$$\alpha|0\rangle + \beta|1\rangle \rightarrow \alpha|000\rangle + \beta|111\rangle \quad (6)$$

- ▶ Protects against bitflip errors.
- ▶ Does not protect against phase-flip errors.

Topological error correction

- ▶ Practical: Only need nearest-neighbour interactions on a two-dimensional manifold.
- ▶ Only homologically non-trivial operators can affect encoded logical qubit. E.g. toric code/surface code
- ▶ Topological order: Homologically non-trivial observables cannot distinguish $|0_L\rangle$ and $|1_L\rangle$.

Toric code

- ▶ Physical qubits are arranged on the edges of an $L \times L$ square lattice with periodic (toric) boundary conditions.
- ▶ Set of commuting check operators $B_p = \bigotimes_{i \in p} Z_i$ and $A_v = \bigotimes_{i \in v} X_i$.
- ▶ Codespace is the simultaneous $+1$ eigenspace of all B_p and A_v operators.

Toric code

- ▶ The check operators generate a group called the *stabilizer* \mathcal{S} of the code.
- ▶ If $|\psi\rangle$ in the codespace and $g \in \mathcal{S}$ then $g|\psi\rangle = |\psi\rangle$.
- ▶ Elements of the stabilizer are homologically trivial loops.

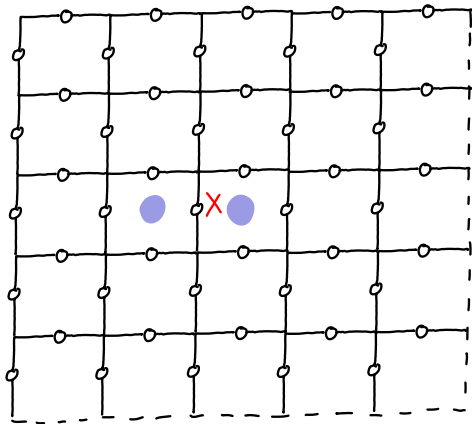

Logical operators

- ▶ The operators \bar{Z}_1 and \bar{X}_1 commute with every element in the stabilizer, but are not in the stabilizer.
- ▶ The logical qubit states $|0_L\rangle_1$, $|1_L\rangle_1$ are defined as the ± 1 eigenstates of \bar{Z}_1 in the code space.
- ▶ \bar{Z}_2 and \bar{X}_2 wrap around the torus in the other way.

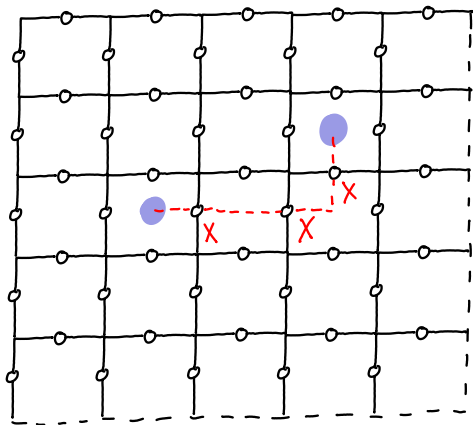

Error-correction with the toric code

- ▶ A single X error flips adjacent plaquettes.

Error-correction with the toric code

- ▶ A chain of X or Z errors will only flip the checks at the ends of the chain.
- ▶ The set of flipped checks is called they syndrome.

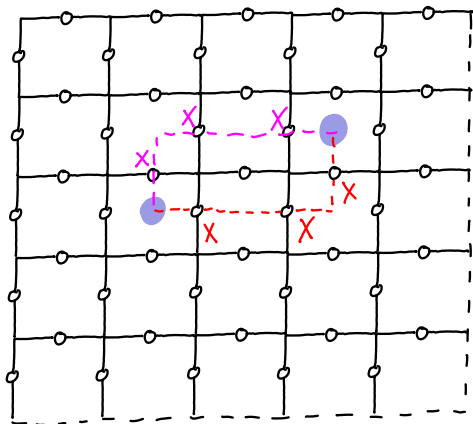

Error-correction with the toric code

- ▶ A chain of X or Z errors will only flip the checks at the ends of the chain.
- ▶ The set of flipped checks is called they syndrome.

Error-correction with the toric code

- ▶ We can correct the error by matching the flipped checks (Z-checks with strings of Pauli X and vice versa).

Error-correction with the toric code

- ▶ However in doing so, it is possible to apply a non-trivial operation to the encoded qubits (a logical error).
- ▶ A classical *decoding algorithm* is used to choose which correction to apply. It's goal: return to the code space while minimising the probability of a logical error.

Minimum-weight matching decoder

- ▶ Minimum-weight matching: Consider B_p and A_v syndromes separately. For each apply a correction with smallest possible weight.

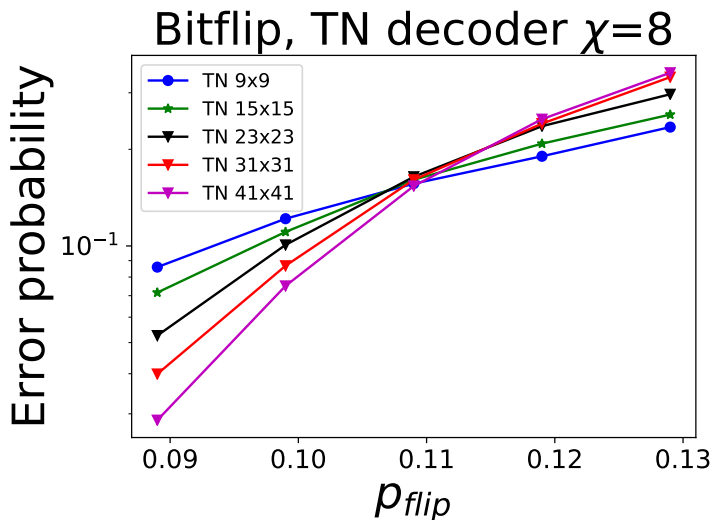

- ▶ Works well provided the number of errors is not too large.

Threshold

- ▶ If the error rate is below certain value, called the *threshold* we can exponentially suppress errors on the logical qubits by increasing the lattice size.
- ▶ The threshold depends on a number of factors:
 - ▶ The code being used
 - ▶ The decoder
 - ▶ The type of noise

Results: Bitflip

- ▶ Each qubit has independent probability p_{flip} of being flipped.

Full fault tolerance

- ▶ In the real world, gates, measurements, state-preparation are all imperfect and prone to errors.
- ▶ Remarkably, an error threshold exists even when all the operations in error correction are faulty.

Universal quantum computation

- For universal quantum computation, it must be possible to perform a universal set of gates in a fault-tolerant way.

Figure: Performing gates by lattice surgery (From "A Game of Surface Codes: Large-scale Quantum Computing with Lattice Surgery" Litinski D. 2019)

Open problems

- ▶ Error correction is extremely expensive: What can we do to lower the cost?
 - ▶ Reducing noise in hardware
 - ▶ More efficient codes
 - ▶ More efficient decoding

Summary

- ▶ Quantum error correction is a way to actively protect quantum information against noise.
- ▶ Quantum error correction involves encoding a single logical qubit into many physical qubits and performing operations that detect and correct errors.
- ▶ Quantum error correction is challenging: it requires a huge number of extra qubits and operations.
