A Kilonova Associated with the Short GRB 130603B

Andy Fruchter (STScI)
N. Tanvir, A. Levan, R. Hounsell et al.
LGRBs are Decisive

- Long bursts (LGRBs) are largely found on rapidly star-forming irregular galaxies (Fruchter+1999, Bloom +1999...)

- LGRB hosts are generally dominated by extremely young stellar populations (<10 Myr) (Levesque+ 2010) and are largely metal poor (≤ 1/3 solar) (Modjaz+ 2008)

- LGRBs are preferentially found on brightest regions of their hosts (Fruchter et al. 2006)

- Most, if not all LGRBs, are associated with Type Ic SNe (Hjorth + 2003, Stanek + 2003 ...).
SGRBs Are Tentative

- SGRBs are found in all types of galaxies, from star-forming dwarfs to ellipticals (Fox + 2005, Bloom + 2005)

- Stellar populations of hosts have typical ages of few hundred Myrs (Liebler & Berger 2010)

- No SGRBs are associated with SNe (to very strong limits in many cases)

- SGRBs are widely distributed on hosts (Berger & Fong 2010); ~ 10% may be hostless
You say Macronova, I say Kilonova

• Merging neutron stars should throw out few percent of their mass as tidal tails -- this material would be hot, and neutron rich. (Eichler + 1989, Li & Paczynski 1998,)

• No search had yet found such a “nova”

• Barnes and Kasen (2013) proposed the nova would be very red due to extraordinary optical depth of r-process ejecta.
First SGRB Host Absorption Spectrum of GRB 130603B

Figure 1: (a) Spectrum of the afterglow of GRB 130603B obtained using the OSIRIS instrument on the 10.4 m GTC telescope 7.4 hr after the burst onset. The contribution of the host galaxy was subtracted using a second spectrum, that was obtained 5 days later when the afterglow had faded away. Panel (b) shows this second spectrum of the host galaxy. Dotted vertical lines indicate the location of some of the absorption and emission features. Grey vertical bands mark the position of strong telluric features.

Do **We** Say Kilonova?

- Absolute magnitude of J=-15.35 at 7 days is in good agreement with KN models -- and makes it in luminosity at least a “kilonova”

- Timescale of “bump” consistent with KN predictions

- But our data are not as constraining as one might like
GRB 080503

Perley et al. 2009

Hascoët et al. 2012
Et tu, 060313B?

The Nearest(?) SGRB

GRB 080905a  z=0.12? (480 Mpc)
Kilonovae as Markers

- Advanced LIGO should find NS mergers out to \( \sim 200 \) Mpc

- Will have error circles of 10s of square degrees

- But at 200 Mpc, 130603B would have had \( J \approx 21, I \sim 22-25 \). Can be found from ground but will likely require image subtraction (so not trivial) and large aperture (Subaru, LSST?)
Conclusions

- The simplest explanation for our observations is a kilonova.
- Our results do not eliminate the possibility of a rare afterglow phenomenon, but we appear to be confirming a PREdiction.
- There is a good chance we will have an opportunity to repeat the experiment within another eighteen months.
